## Supplement

Fig. 1. When we find approximate matches of reads of length $L$ in genomes, our approach compares 2 -gram frequency vectors of the read with 2 -gram frequency vectors of length $L$ windows in the genome. If the read, $t$ in this figure, derived from position 1 of the genome $s$ by a deletion of size $k$ (blue), the last $k$ positions of $t$ match $s[L+1, L+k]$. Affine edit distance is not tight if $s[L+1, L+k]$ at least partially matches the deletion. We argue that the probability of this happening is low.

Probability of catastrophic failure: For edit operations which affect positions $q$ letters apart, it is easy to show that the inequality $L_{1} \leq$ AED is sharp, that is $L_{1}$ gives the edit distance with affine gap costs. Consequently finding matches of minimal $L_{1}$ prefers matches with fewer indels over matches with frequent substitutions. However, the lower bound can be still arbitrarily bad (when one string is a rotation or transposition of another), but the probability is small. The 2 -gram frequency vectors can be naturally viewed as the sufficient statistics of a first-order Markov chain on nucleotides, and we will view all our points, both reads and genomic positions, as first-order Markov chains.

Consider the fixed $L$-length window $s$ (Fig. 1) in the reference genome and its $q$-spectrum $c_{q}(s)$. How is $c_{q}(s)$ altered by the deletion? A total of $k+1$ subtractions by one-one for each pair of nucleotides from one position before the deletion to one position after the deletion-is applied to not more than $k+1$ coordinates of $c_{q}(s)$. As $t$ is also of length $L$, the deletion has to be balanced by $k$ additional characters from $s$. This introduces $k-1$ pairs (red in Fig. 1) at the end, one containing the character before and the character following the deletion and one pair $\left(s_{L}, s_{L+1}\right)$, which
were not present in $s[1: L]$. These $k+1$ additional pairs give a total of $k+1$ additions of 1 to not more than $k+1$ coordinates of $c_{q}(s)$. It can happen that these $k+1$ subtractions and $k+1$ additions exactly cancel, yielding $L_{1}(s, t)=0$ even though the Levenshtein distance $\mathrm{ED}(s, t)=k$. Under the Markov assumption we can now compute an upper bound for the probability $P\left(L_{1}(s, t)=0 \mid \mathrm{ED}(s, t)=k\right)$ if we consider exactly one deletion of length $k$ as in Fig. 1. If we look at a single 2 -gram within the deletion then the probability that it appears in the red part in Fig. 1-hence the subtraction of the count due to the deletion and is offset by the addition of the countis largest, when it is the most frequent 2 -gram. Assuming the two subtractions involving pairs across the border of the deletion in $s$ and the pairs covering the deletion in $t$ and across the boundary to the red part in $t$ cancels out, the probability of finding exactly the $k-1$ deleted counts (contained inside the deletion of $s$ ) compensated by the added counts at the end of $t$ is bounded from above by

$$
\begin{aligned}
P\left(L_{1}(s, t)=0 \mid \mathrm{ED}(s, t)=k, \text { one deletion }\right) & \leq\binom{ k-1}{c_{A}, c_{C}, c_{G}, c_{T}} P_{1}^{*} \\
& \leq \frac{(k-1)!}{\left(\frac{k-1}{4}!\right)^{4}}\left(P_{2}^{*}\right)^{k-1}
\end{aligned}
$$

where $c_{A}, c_{C}, c_{G}, c_{T}$ are the nucleotide counts in the deletion, $P_{1}^{*}$ is the maximal probability of a realization of length $k-1$ produced by the underlying Markov chain and $P_{2}^{*}$ the maximal transition probability in the Markov chain.

Memory reduction: We create $d$-dimensional $q$-gram frequency vectors by shifting a window of size $l$ (read length) over a genome of size $G$. This naive approach uses $O(G d)$ amount of memory. To reduce this large memory requirement for storing count vectors, we apply two techniques. First, we only consider every $g$-th genomic window for computing frequency vector, which brings down the memory requirement to $O\left(\frac{G d}{g}\right)$. Second, we observe that consecutive $g$-th windows can have at most $2 g$ differences in their frequency vectors. We exploit this observation by not storing the left $\alpha$ vectors and right $\alpha$ vectors of a particular vector $V$. Instead we define these $2 \alpha$ vectors by their differences from $V$. When we need these vectors in later stages we compute them on-the-fly. After applying these two ideas, the total memory requirement for storing count vectors is $\frac{G d}{g(2 \alpha+1)}+\frac{2 G \alpha(\alpha+1)}{2 \alpha+1}$.

Fig. 2. Effect of different parameters on TreQ. Simulated datasets S1, S2, S3, and S4 (for details see Section: Discussion) of read length 100bp are tested with different parameter choices for TreQ. The memory requirement for TreQ comes down from 150GB $(\tau=1, \alpha=0)$ to 40GB ( $\tau=4, \alpha=2$ ) while a careful selection of $\beta$ achieves equivalent mapping accuracy in similar amount of time.
